Short communication

Rapid long-distance migration in Norwegian Lesser Black-backed Gulls

Larus fuscus fuscus along their eastern flyway

We studied the long-distance migration of Lesser Black-backed Gulls Larus fuscus fuscus breeding in northern Norway along their eastern flyway using geolocators in 2009 and 2010. The majority of birds wintered in lakes in East Africa and the southeast Mediterranean was the most important stopover area. Larus f. fuscus along the eastern flyway travelled at a net travel speed of 399 and 177 km/day during the autumn and spring migration, respectively, higher than published travel speeds for Dutch Larus fuscus migrating along the western flyway. The results suggest that the long-distance migratory Norwegian L. f. fuscus seek to minimize time spent in transit, whereas lower travel speed during northerly spring migration may reflect differences in wind patterns or food conditions between spring and autumn.

Keywords: animal movements, migration strategies, migratory stopover.

Many bird species appear to minimize the time spent on migration rather than the associated energetic costs (Alerstam & Lindström 1990), perhaps because of the high risks encountered en route to wintering grounds (Strandberg et al. 2010), the need to allocate time to other activities (Buehler & Piersma 2008) or because of the benefits of early arrival in breeding or winter areas (Norris et al. 2004). However, there is high variation in flight modes (e.g. flapping, soaring) and migration strategies (e.g. speed, distance, routes) between and within bird families (Klaassen et al. 2012). For example, the gulls (Laridae) are considered to use flapping flight as well as thermal- and ridge-soaring flight (Rayner 1988) on migration. In addition, as generalist foragers they may find food in almost any habitat along their migration routes (Olsen & Larsson 2004), which may affect time spent on migration (e.g. Klaassen et al. 2012).

Lesser Black-backed Gulls Larus fuscus breeding in the Netherlands were predicted to show a time-minimizing migration strategy, with birds taking the shortest possible route, having few stopovers and travelling at a high speed (Klaassen et al. 2012). Instead, using satellite transmitters, Klaassen et al. (2012) found that the gulls made substantial detours from the shortest route and travelled at low speeds during the autumn and spring, respectively, was the lowest yet recorded in any migrating bird. The authors concluded that these gulls minimized energy expenditure during their relatively short migration (500–2800 km) and stated that it is not known if such a migration strategy is commonplace among gulls, or whether other populations of Lesser Black-backed Gulls with different migration routes, such as those from Scandinavia, behave similarly.

The nominate subspecies of the Lesser Black-backed Gull Larus fuscus fuscus breeds in Norway and around the Baltic Sea, and winters in east-central Africa (Kilpi & Saurola 1984, Helberg et al. 2009). They therefore have the longest migration of any Lesser Black-backed Gull population (up to 7600 km), but so far there has been no detailed study of the route or travel speed of individual gulls. We examined the migration movements of Lesser Black-backed Gulls from northern Norway, using light and temperature data from geolocators (Global Location Sensor or GLS loggers). Because Scandinavian gulls travel over much longer distances and probably cross areas with little food (Helberg et al. 2009, Kylin et al. 2011) we predicted that their migration strategy would be different, with higher travel speed and fewer stopovers, from that recorded for the much shorter distance migrants from the subspecies breeding in the Netherlands (Klaassen et al. 2012).

METHODS

Lesser Black-backed Gulls were caught at Horsvær (65°19′N, 11°37′E), a small archipelago in Helgeland (Nordland County) in northern Norway. Up to 400 pairs of gulls breed on seven small islands when conditions are good. At our arrival in the study area in mid-June 2009 and 2010, we marked all occupied nests and trapped incubating birds using walk-in traps (Bustnes et al. 2008). The birds were ringed with steel and alphanumeric colour rings, and geolocators were fitted to the colour rings by cable ties.

GEOLOCATORS

Using geolocators it is possible to calculate the position of birds (twice per day) from light level readings with reference to calendar date, with an average error of ~185 km (Phillips et al. 2004). In June 2009 and 2010, eight and 12 GLS loggers (mk15, 2.5 g; British Antarctic Survey, Cambridge, UK) were mounted on breeding birds. Five GLS loggers were retrieved in 2010, and two in 2011. Six loggers had been on for 1 year and contained data for the complete migration. One logger had been on from 2009 to 2011, and contained data until 27 March 2011. The data were downloaded and processed with the BASTARAK software package (Fox 2010). Following Frederiksen et al. (2012), we calculated positions initially using a range of sun elevation angles between $-1.5^\circ$ and $-4.5^\circ$. Birds were assumed to stay close to the colony at the end of the breeding season (25 July–5 August), and the smallest bias in latitude was obtained with a light-threshold of 10 and a sun elevation angle of $-2.5^\circ$. Hence, this angle was used for all loggers. Furthermore, it provided the best results for the remainder of the year, including a distribution at the end of the spring migration that was centred on the breeding colony.

Although longitudes were unaffected, estimates of latitude were unreliable for around 2 weeks before and after the equinoxes. However, the loggers recorded temperature when being in salt water (one record after 20 min continuous submersion and a second and last record after 40 min), which can be used to improve latitude estimation where there are differences between water masses or a clear latitudinal gradient in sea surface temperatures (Bost et al. 2009). Therefore, we compared temperature readings from the loggers (95% confidence intervals of the mean) with weekly sea surface temperatures (SSTs) extracted from 1° grids in the Norwegian Sea (65–66°N, 11–12°E), Baltic Sea (55–56°N, 18–19°E), Gulf of Bothnia (62–63°N, 19–20°E), Black Sea (42–43°N, 30–31°E), Mediterranean Sea (32–33°N, 32–33°E), Gulf of Suez (28–29°N, 32–33°E) and Red Sea (26–27°N, 34–35°N) obtained from the IRI/LDEO Climate Data Library (http://iridl.ldeo.columbia.edu/SOURCES/.NOAA/.NCEP/.EMC/.CMB/.GLOBAL/.Reyn_SmithOIv2/.weekly/).

Stopovers were identified when birds rested on seawater and the loggers recorded temperature. Depending on whether this occurred outside or within the equinox periods, the stopover sites were allocated to one of the above-mentioned ocean regions based on information on latitude, longitude and SST or longitude and SST, respectively.

We calculated the geographical mean, using spherical trigonometry, for all positions in December–January to identify individual wintering areas (Fig. 1). We used a conservative approach when calculating distances, using great circle distances between the colony and the wintering areas, via the stopover sites (Fig. 1). We therefore focused on the net travel distance and speed (net travel distance divided by number of days) of the tracked birds, as we could not obtain reliable daily travel estimates because parts of the migration occurred during the equinoxes.

During the equinoxes, we used the longitude estimates and SSTs to aid the determination of the timing of migration. Timing of departure from the breeding grounds and arrival at the Mediterranean (including stopovers) was successfully determined for all seven birds, except one during autumn (Table 1). Timing of arrival and departure in East Africa, however, could only be determined for three and two birds (of six), respectively. All but one of these birds arrived or departed outside the equinox periods when both latitude and longitude estimates were reliable. Timing of departure

Figure 1. Stylized migration route of Lesser Black-backed Gulls Larus fuscus fuscus from a Norwegian colony via stopover sites (red circles) to the wintering grounds in East Africa and the Mediterranean Sea (filled circles, each colour representing a different individual). The path is shown for the individual wintering furthest south, and represents the net migratory distance.
from East Africa for one bird that departed during the spring equinox could be determined because this bird wintered in a salt water lake that has a surface water temperature considerably higher than the Mediterranean in spring, which allowed us to estimate its timing of departure. These birds spent on average 4 (3–5) and 11.5 (10–13) days migrating between the Mediterranean and the wintering areas during autumn and spring, respectively. These values were applied to the remaining birds to estimate the total time spent on migration. Although this reduces the variance in net migration speeds, it is unlikely to have more than a marginal effect on the overall mean.

RESULTS
The final destination of all Lesser Black-backed Gulls that were tracked was East Africa (Uganda or South Sudan), except for one that spent the entire winter in the southeast Mediterranean Sea (Fig. 1). For the birds wintering in East Africa, the mean net migratory distance from the breeding colony to the individual wintering areas was 7239 km (se 133, n = 5) and 6632 km (se 378, n = 2) in 2009 and 2010, respectively (Table 1, Fig. 1). The birds took about 3 weeks to reach their wintering areas in East Africa, including brief stopovers in the Baltic Sea and/or the Black Sea, and 9 days in the Mediterranean (Fig. 1, Table 1). The mean net travel speed between Norway and East Africa was 399 km/day (se 378, n = 4) and 315 km/day (se 352, n = 2) in 2009 and 2010, respectively (Table 1).

The Gulls departed on the spring (return) migration from East Africa in March or April and reached the Mediterranean by end March to mid-April. In 2010, the Mediterranean was the main stopover site, with birds staying there on average for 20 days (se 2.1, n = 5; Table 1), compared with periods of 0–2 and 2–12 days in the Black Sea and the Baltic Sea/Gulf of Bothnia, respectively. In 2011, in contrast, the one tracked bird spent only 3 days in the Mediterranean, compared with 16 days in the Black Sea and 13 days in the Baltic Sea. The overall spring migration lasted 6 weeks, with mean net travel speeds of 177 km/day (se 12, n = 5) in 2010, and net travel speed of 141 km/day (n = 1) in 2011 (Table 1).

DISCUSSION
Lesser Black-backed Gulls of the subspecies fuscus from Norway are long-distance migrants, estimated conservatively to travel at least 6295–7585 km to reach wintering grounds in East Africa (Table 1). The only other long-distance transequatorial migrants among the 43 species of gulls in Europe, Asia and North America are Sabine’s Gull Larus sabini and Franklin’s Gull Larus pipixcan (Olsen & Larsson 2004, Stenhouse et al. 2012). The migration strategies of the birds we tracked were very different from those of Lesser Black-backed Gulls from the Netherlands (Klaassen et al. 2012). However, the two subspecies travel over different habitats and have different flight distances from their breeding sites, so variation in flight strategies might be expected. Gulls in our study seemed to follow the shortest route from Norway to East Africa, including long overland flights, whereas the Dutch gulls predominantly followed the coast. Moreover, Norwegian gulls had few stopovers (2–3), the longest being up to 12 and 24 days in autumn and spring, respectively. The Dutch gulls, in contrast, stopped frequently, most individuals on at least one occasion for > 14 days, and on average for 77 days in total (Klaassen et al. 2012). The use of coastal areas and long stopovers enabled the latter to take advantage of feeding opportunities along the route, which was less of a possibility for Norwegian gulls, as they fly mainly

*Timing and speed of autumn migration could not be estimated for bird B. The logger attached to bird F stopped in spring 2011 and parameters for spring migration could not be obtained. *Bird C spend the entire winter (198 days) in the Mediterranean Sea.
over forests and deserts (see also Schmaljohann et al. 2008). As a result, the Norwegian gulls had a much higher net migratory speed (399 and 315 km/day in autumn 2009 and 2010, respectively) compared with Dutch gulls (44 km/day). The complete autumn migration (~7000 km) of Norwegian gulls took 3 weeks. In spring, the Norwegian gulls migrated substantially more slowly than in autumn, yet still almost twice as fast as those from Netherlands. The lower speeds during spring may reflect less favourable wind patterns for northern migration along the eastern flyway (Shamoun-Baranes et al. 2003, Kemp et al. 2010), and birds may postpone departure until wind conditions are optimal for northern flight. Alternatively, it could reflect a greater need to build up body reserves before returning to the breeding colony. Indeed, food availability in their breeding areas may be unpredictable, and often scarce (Bustnes et al. 2010a,b) and the gulls have no way of assessing feeding conditions beforehand.

One issue regarding the comparison between the two studies is the use of different technology. Klaassen et al. (2012) used Argos GPS loggers with very high accuracy, whereas we used geolocators, which provide locations of much lower spatial and temporal resolution. We did not calculate daily point-to-point travel speeds, but instead calculated great circle distances between the colony and the wintering areas via the stopover sites, divided by migration duration. This conservative approach seems justified; there is little reason, given the lack of feeding opportunities, to expect that the gulls would have diverted much from the shortest routes, and hence distances and speeds are unlikely to be greatly underestimated. Moreover, according to an unpublished study, one Finnish gull with a satellite-transmitter flew 3500 km nonstop from the Nile Delta to Lake Victoria in 92 h (J. Kube, A.J. Helbig, R. Juvaste, C. Rabek & P. Saurola unpubl. data), which is similar to the time taken by the Norwegian birds (3–5 days) for the same journey. This suggests that our estimates of flight speed are reasonable. One great advantage of GLS loggers is the small size, which makes interference with flight capability highly unlikely.

This study highlights a striking intraspecific difference in migration strategy in the Lesser Black-backed Gull, depending on the distance travelled. Birds from the Netherlands, with short travel distances, seem to minimize energy expenditure, migrating slowly to take advantage of feeding opportunities along the route, and to move only when conditions are favourable (Klaassen et al. 2012). In contrast, the long-distance migrants from northern Scandinavia travel rapidly in order to reach the productive freshwater habitats of East Africa. This suggests that they are minimizing the time spent on migration, and as such the population conforms more closely to accepted theories on the evolution of bird migration patterns (Alerstam & Lindström 1990). Furthermore, time spent on migration seems to be modulated by additional factors. For example, if wind patterns are favourable it may be beneficial to reduce the duration, whereas good feeding conditions at stopover sites may make it better to stay longer to increase nutrient reserves. An example of potential modulation of migration strategy is that Dutch and Norwegian gulls, respectively, increased and decreased speeds during spring migration.

We thank two anonymous reviewers for comments that greatly improved an earlier draft of the manuscript. The study was funded through the Norwegian Seabird Research Program SEAPOP and the Fram Centre.
